

Globalization and the Environmental Spillovers of sectoral FDI

Nadia Doytch* and Merih Uctum**

November 2012

Abstract

We analyze the environmental impact of capital inflows and investigate different hypotheses: the Halo Effect (FDI improves environmental standards by bringing in clean technology), the Pollution Haven argument (capital flows to poor countries with environmentally lax standards) and the Environmental Kuznets Curve, EKC (pollution increases with economic growth, and declines when wealth reaches a certain threshold). We find: (i) a differential industry effect: FDI flows into manufacturing support the pollution haven hypothesis, while those flowing into services support the halo effect hypothesis; (ii) an income inequality effect: on aggregate, FDI flowing into low and middle income countries degrades the environment, while flows to high-income countries benefit the environment and support a halo effect; (iii) EKC results hold if capital flows into agriculture and services industries in relatively lower income countries and if flows go into mining and manufacturing in wealthier economies.

Key Words: Sectoral FDI, environmental spillovers, dynamic panel.

Introduction

The 2008 financial crises and extreme climate events such as floods, hurricanes and droughts that the world has been experiencing with an increased frequency since the beginning of the 21st century have one common message: with globalization, extreme events are no longer extreme and can hit both industrialized and developing economies alike. The financial crisis that originated in the United States has transformed into a global recession and climate change is being felt throughout the world at an ever increasing rate.

The controversy surrounding the climate change and the ecological impact of human activity is receding. Public opinion is gradually acknowledging the role of the human factor leading to extreme temperatures and soaring levels of atmospheric carbon dioxide (Figure 1). Business and investors are facing increased restrictions and regulations from authorities forced to cut emissions. Such regulations are already implemented by Australia that imposed a carbon trading scheme and the UK that requires the listed companies to report their carbon footprint. Managing the climate-generated risk is becoming one of the important objectives of companies and therefore, many businesses and insurers are supporting clear measures and regulations.

Globalization and environment are linked in several ways both in the literature and in common discourse. Traditionally, globalization was considered the catalyst to environmental degradation through two channels. (i) *The Pollution Haven, or race-to-the bottom*. Accordingly, in an environment of liberalized trade flows, tightening environmental regulation in developed countries can shift polluting industries to countries with relatively lax regulation; (ii) *The “Environmental Kuznets Curve”* (EKC), described by an inverse U-shaped relation between pollution and income, states that economic growth (often associated with globalization) increases pollution in low-income economies until their level of development reaches a certain level, and decreases it thereafter.

Both channels, however, are mitigated by the more recent literature, which revealed what is called a “halo effect”. *The Halo Effect hypothesis* states that multinational companies disseminate superior knowledge, which applies environmentally friendly practices while improving the environmental performance of domestic business. This view parallels the literature examining the productivity gains generated by foreign firms in host country via spillovers of knowledge, knowhow, etc.

For a regulatory body it is crucial to know which effect is triggered by companies, whether foreign or domestic. For business, especially those operating internationally, it is critical to know its impact on carbon emissions and manage its risks. In this study we propose to understand the impact of globalization on the host country’s environment by disentangling the three effects (EKC, Pollution Haven and Halo Effects). Often the foreign direct investment (FDI) is directly associated with globalization and all three effects are pertinent for multinational companies that invest in physical plants and

equipment, contributing to the production and growth in host countries. We thus look at the impact of FDI inflows on air quality, controlling for nonlinear income terms. While our goal is to assess specifically the halo effect and the EKC, our analysis also fits in the pollution haven strand of the literature because we examine the role of the FDI and its effect on the pollutants in the host country.

Contribution of this study to the literature

The review of the literature highlights various drawbacks that prevent establishing a clear relation between pollution and capital flows. First, most studies that examined the impact of globalization on the environment, considered the three effects separately, with a plethora of data and samples at the firm level or country level, which makes it virtually impossible to draw any consistent conclusion. Second, the methodology adopted is time-averaged cross-section approach, which is inadequate to analyze a dynamic phenomenon such as greenhouse gas emissions with little or no reversion. Finally, idiosyncratic shocks to different sectors may outweigh the regional shocks and conceal differences at the industry level, and may explain the reason behind inconclusive results in the literature. We address the drawbacks by adopting a unified framework and a dynamic model that allows the analysis of all three effects over time and a long span of data covering multi-country and industries. We identify the channels through which the halo and the pollution haven effects manifest and investigate the EKC effect, controlling for the type of FDI inflows and the level of development of the economies.

The work on the environmental impact of total FDI uses an aggregate measure, which conceals sectoral effects. At the other end of the spectrum, the analyses that examine the investment decisions at the firm level miss the sectoral impact of these decisions and the intersectoral spillovers. We conduct a comprehensive industry analysis using the largest and the longest data span available. Growth studies have shown that FDI that flows to different sectors have different impact on sectoral and aggregate growth, often manifesting themselves through spillovers to different industries (Doytch and Uctum, 2011). Likewise, we expect different effect by different sectoral FDI inflows on pollution (e.g., financial FDI might impact the environment even though it goes to a non-polluting services industry).

Many of the previous studies struggle with endogeneity and simultaneity. The explanatory variables used in the empirical studies are likely to influence each other, or the dependent variable can affect the independent variables. For example, a country with restrictive environmental laws may reduce pollution but they may be also a reaction to pollution; or pollution may change by FDI but it can also determine the amount of FDI inflows. We can also have independent variables affecting each other: laws may influence the flow of FDI, high growth can encourage FDI. The simultaneity problem can create substantial biases in the estimates, which make results meaningless. To address this issue, we adopt a dynamic panel data approach (Arellano and Bover, 1995;

Blundell and Bond, 1998), a methodology that circumvents this problem.¹ Another advantage of the GMM estimator is that it exploits both the time series dynamics and the pooled country characteristics of the data while controlling for endogeneity and omitted variable biases. This allows us to retain the time-series aspect of the data and the dynamic aspects of changes in the sectoral flows of FDI, a feature that the traditional approach of the cross-sectional time-averaging methodology is not able to capture.

We show that the capital flow-pollution nexus results depend critically on the type of FDI flows and income distribution. First, we find a differential industry effect: foreign investment that flows into clean industries such as services support the Halo Effect hypothesis, while those flowing into traditionally dirty industries such as manufacturing are consistent with the Pollution Haven hypothesis. Second, we uncover an income inequality effect: In general, foreign investment flowing into poorer countries has harmful effects on environment, while those flowing to richer countries have a beneficial effect and support the halo effect. Third, we resolve the ambiguity in the EKC literature. As countries become wealthier, the EKC is supported (i.e. pollution decreases with economic development) in countries where capital was flowing in dirty industries, such as mining and manufacturing. If the flows are in traditionally clean industries, the EKC is not supported. This result shows that the inconclusiveness in the literature is removed if the industry specificity of FDI is accounted for.

GDP shares of FDI across sectors and income levels

Figure 1 displays the FDI net flows since 1995 separated as all countries (upper left panel), high-income countries (upper-right panel) and middle-income and low-income countries (lower panels). Since the 1990s, the FDI/GDP ratio has been increasing up until 2007 and abruptly fell during the crisis. The substantial rise in the early 2000 (and the subsequent fall) is predominantly led by FDI in financial services sector, followed by the nonfinancial services sector. FDI inflows into manufacturing, mining and agriculture, the traditionally dirty industry sectors have been declining or stable and insignificant. On this account, we should expect, on average a reduction in the pollution trends, since the services sector uses relatively clean technology.

Disaggregating the data according to income distribution, however, gives quite a different picture. The sectoral FDI/GDP patterns in the high-income countries follow closely those of the total sample, suggesting that FDI is likely to have a halo effect in wealthy economies. This is also consistent with the EKC hypothesis. The aggregate pattern is somewhat replicated in the middle-income countries, which enjoy a rise in the

¹ One notable exception is the study by Frankel and Rose (2005), which examines the effect of trade (openness) on environment. Endogeneity of trade and income is controlled for by instrumental variable approach within a cross-country estimation in 1990. Although our approach is parallel to Frankel and Rose, it differs in several ways. First, we do not take a single year of data but examine the evolution of the phenomenon through time, over the course of 38 years. Second, our analysis involves dynamics and is not static. Third, our analysis is sectoral and thus is able to capture the intersectoral spillovers.

nonfinancial services FDI inflows. However, the small but positive trend in the polluting industries such as mining mitigates the halo argument. The case with low-income economies, however starkly contrasts with the rich countries. Despite a general decline in overall FDI flows, substantial increase in inflows into mining in the early 2000 and a leap in late 2000 dominate all flows to other industries. Considering that mining is a dirty industry, this observation suggests that support for the pollution haven argument is not that farfetched. Our analysis examines these interactions rigorously and tests whether such causalities are supported by the data.

Literature Review

All three hypotheses discussed above, namely, the Halo Effect and the Pollution Haven hypotheses, and the Environmental Kuznets Curve (EKC) are interrelated.

The halo effect follows the productivity literature in spirit, which examines the productivity spillovers by FDI both at the firm and macroeconomic levels.² The rationale behind potential environmental spillovers is that the possibility that multinational corporations (MNCs) encourage the dissemination of environmentally clean technologies and management practices (Garcia-Johnson, 2000). This occurs if the foreign firm engages in contracts only with environmentally responsible domestic counterparts. This may happen under shareholder pressure at the MNC or because of practices established at the MNCs based on its home country environmental regulations and standards. Further environmental knowledge can disseminate through the movement of trained workers from foreign to domestic firms (Görg and Strobl, 2004) or because of a direct competition of domestic firms with the MNCs.

The literature on environmental spillovers from FDI confines mainly to case studies of specific countries' manufacturing industry firms. The evidence with respect to the halo hypothesis has been mixed (Paigel and Wheeler, 1996). In a limited Indonesian manufacturing firm study conducted on plant-level for the period 1989-90 with respect to water pollution, Hartman et al. (1997) conclude that "abatement... is... unaffected by foreign links (in ownership financing)". Dasgupta et al. (2000) examine the impact of regulation, plant-level management policies, and other factors on the environmental compliance of Mexican manufacturers and find no significance for the foreign ownership variable as well.

² Firm level studies find mixed evidence of productivity spillovers, ranging from limited positive (Haskel et al., 2007; Blalock and Gertler, 2003), to no or negative spillovers (Aitken and Harrison, 1999; Gorg and Strobl, 2001; Lipsey, 2003, 2004). At the aggregate level, the evidence has been overwhelmingly in support of positive impact by FDI inflows (Borensztein et al., 1998; Blomstrom et al., 1994, Alfaro et al., 2008). The sectoral level analysis reconciles these inconsistent results. Manufacturing FDI has positive spillovers that spur through its own sector, while financial services have a positive effect that spreads through services, whereas nonfinancial services drain resources from manufacturing and can have a negative effect on growth (Doytch and Uctum, 2011).

More recently, however, Eskeland and Harrison (2003) analyze outbound US FDI and find that foreign plants are significantly more energy efficient and cleaner in their energy uses than their domestic partners, which supports the halo hypothesis. Another supporting evidence for the halo hypothesis comes from the study by Cole et al. (2008) who assess the extent to which foreign ownership influences the energy intensity of firms in Côte d'Ivoire, Mexico and Venezuela, and Ghana. In each country they find that foreign ownership reduces the energy intensity of plants. Finally, in a sample of Argentinean firms, Albornoz et al (2009) find supporting evidence that (i) foreign-owned firms are more likely to implement environmental management systems compared to domestic firms; (ii) firms that supply sectors with high multinationals and regularly meet with their customers are more likely to adopt environmental management systems; (iii) firms' absorptive capacity, ownership and export status also influence the extent to which they benefit from environmental spillovers.

EKC, the second but the older line of research in environmental economics, states that the quality of the environment worsens as the economy grows and once a certain threshold is reached, it starts improving, resulting in an inverse U-shaped pollution-GDP per capita pattern. This line of argument parallels that of the structural change in development whereby the share of manufacturing in the economy grows in the initial phase of development but later decreases as the services overtake the role of manufacturing in growth. The implication of EKC is that environmental quality increases with economic growth after a threshold. The estimation model consists typically of the cubic or quadratic income terms and their lagged values, and a vector of control variables including policy, trade, and institutional variables. The initial research corroborated the EKC argument (Selden and Song, 1995, Shafik, 1994, Grossman and Krueger, 1995, Holtz-Eaking and Selden, 1995, Hilton and Levinson, 1998). More recent research, however casts doubt on the existence of a neat inverse U-shaped relation (Stern, 1998, Harbaugh et al. 2002, Hettige et al. 2000).

The original Pollution Haven hypothesis (Copeland and Taylor, 1994) states that as trade is liberalized, industries that pollute shift from rich countries with tight regulation to poor countries with weak regulation and conversely, clean industries migrate towards rich countries. The studies address pollution haven in three ways. (i) Some studies analyze the relation between exports and regulation. Since regulation increases cost, the exports of countries with more stringent regulations become relatively more expensive than those with lax regulation. Therefore their exports decline and their imports of relatively dirty goods rise. In the survey of the literature Jaffe et al. (1995) show that there is an insignificant relation between environmental regulation and exports in manufacturing. Notably, Grossman and Krueger (1993), Tobey (1990) find an insignificant effect, while Kalt (1988) finds a counterintuitive significant effect when manufacturing, the industry with the highest abatement cost, is excluded. (ii) Other studies examine the shift in the pattern of trade in pollution-intensive goods: despite

evidence supporting this hypothesis (Low and Yeats, 1992), this may be due to various factors such as increase in demand for products in the developing countries, development of endowments that develop these industries. (iii) A third group of studies explore firms' location decision. Accordingly, high regulatory costs are likely to deter firms' investment decisions. At the international level, the specific question that is addressed is whether FDI in polluting industries increased towards developing countries. There is some evidence that FDI to the United States is likely to be affected by environmental regulations (List and Co, 2000, Keller and Levinson, 2002, List and McHone, 2000). The literature survey by Jaffa et al., however, indicates either small or insignificant effect of environmental regulations on FDI, and more recent studies find a significant but small effect (List et al., 2004, Becker and Henderson, 2000, Greenstone, 2004, Levinson and Taylor, 2008).

As this brief overview of the literature indicates, most studies and in particular those in environmental spillover literature are conducted at firm level. They give partial, industry-specific insight into the experience of a given country. It is not surprising that literature cannot provide us with a lesson about the global nature of capital flows, which could help us understand events in other contexts. For this, a multi-country, sectoral approach is more appropriate. Our study remedies this weakness and conducts such a sectoral level analysis of the impact of FDI on environmental performance of domestic economies, measured by the levels of air pollution.

Model and Methodology

Several FDI studies in the literature attempted at examining the impact of environmental regulation as an independent variable. The emphasis of these studies falls in the category of the literature on the determinants of FDI. Our emphasis differs in the sense that what we want to examine is how capital flows directly affect pollution in a country, while controlling for the EKC effect. It is clear that these factors are simultaneously determined and their nonlinear interaction is not addressed. The methodology outlined below is designed to control such biases.

We capture the effect of globalization on the environment by controlling for FDI and economic growth:

$$(1) \quad \log(pol_{i,t}) = \beta_0 + \beta_1 \log(pol_{i,t-1}) + \beta_2 \log(y_{it}) + \beta_3 [\log y_{i,t}]^2 + \beta_4 f_{it}^j + \beta_5 corr_t + \beta_6 dens_t + \beta_7 D^t + \mu_i + \varepsilon_{it}$$

with $\mu_i \sim i.i.d(0, \sigma_\mu)$, $\varepsilon_{it} \sim i.i.d.(0, \sigma_\varepsilon)$, $E[\mu_i \varepsilon_{it}] = 0$ and where pol_t is a measure of air pollution, y_t is log of per capita GDP, f_{it}^j is the net capital inflow share of GDP, the subscript j stands for an index for total, agricultural, mining, manufacturing, total services, financial services, non-financial services FDI. The variable $corr_t$ is "control of corruption", a proxy for the institutional variable. It is indexed between 1 and 10, 10

being the highest control of corruption; $dens_t$ represents population density, D^t is a time dummy and μ_i is an idiosyncratic country specific effect.

The level and the square of GDP capture the EKC hypothesis, $\beta_2 > 0$, $\beta_3 < 0$, which leads to an inverse-U shaped relation between pol and y . For the halo effect to hold, the null hypothesis is $\beta_4 < 0$. Albeit not a direct test, a positive sign is consistent with the Pollution Haven hypothesis. We expect $\beta_5 < 0$, that is, for an increase in the control of corruption to improve the institutions of a country and hence to reduce pollution through more stringent regulation to protect the environment, and $\beta_6 > 0$, population density to increase the pollution level.

The simplest methodology, more suitable for cross-sectional than for panel data analysis, is the *pooled OLS* estimation. However, this method fails to account for the time-series dimension of data since it puts all observations together into a “pool” and creates two major flaws: (i) it fails to account for the unobserved country-specific (fixed) effects that cause an omitted variable bias, which then is picked up by the error term; (ii) it fails to control for the potential endogeneity problem. The correlation between some of the independent variables and country-specific effects is again picked up in the error term.

The method of *fixed effects* is designed to control for the unobserved country-specific time-invariant effects in the data. However, it corrects for the possible correlation between these effects and some of the independent variables, conditioning them out by taking deviations from time-averaged sample means. The result of applying such a procedure is that the dependent variable is stripped of its long-run variation – an approach that may be inappropriate for studying a dynamic concept such as capital flows. A technical consequence of the within transformation is that it increases standard errors by exacerbating any measurement errors. This is especially problematic in the case of data with a small time dimension. Another technical issue is that this approach is not informative when we deal with variables with little time variation or ones that are not measured frequently enough. Without an instrument, this approach does not address the problem of endogeneity either, and without time dummies it does not control for the unobserved common time effects among countries, which are then mistakenly picked up by a positive cross-sectional correlation. Overall, both cross-section approaches are not a good tool for analyzing a dynamic relationship between variables and where time-averaging is conceptually not sensible.

The correlation between lagged dependent variables and the unobserved residual is precisely the reason why panel data is to be preferred to cross-sectional when analyzing change in the dependent variable. Cross-section estimates produce a bias, caused by the correlation between $pol_{i,t-1}$ and μ_i , which disappears in samples with large time-dimension but does not disappear with time-averaging. Thus, if such a correlation exists, the true underlying structure has a dynamic nature and time-averaging cross-section

techniques introduce a bias that cannot be removed by controlling for fixed-effects. Therefore, to avoid these pitfalls, we adopt the GMM methodology.

A potential problem of the Arellano-Bond difference GMM estimator is that, under certain conditions, the variance of the estimates may increase asymptotically and create considerable bias if: (i) the dependent variable follows a random walk, which makes the first lag a poor instrument for its difference, (ii) the explanatory variables are persistent over time, which makes the lagged levels weak instruments for their differences, (iii) the time dimension of the sample is small (Alonso-Borrego and Arellano, 1996 and Blundell and Bond, 1998).

An additional necessary condition for the efficiency of the Blundell-Bond system GMM estimator is that, even if the unobserved country-specific effect is correlated with the regressors' levels, it is not correlated with their differences. The condition also means that the deviations of the initial values of the independent variables from their long-run values are not systematically related to the country-specific effects.³ We instrument both income and FDI with GMM style instruments, which will account for reverse causality between these variables and the pollution variable.⁴

Data and Sources

The data are yearly, multi-country and span a long period from 1970 to 2000. Appendix 1 displays the list of countries in the sample. The series come from various sources. The key independent variables are disaggregated FDI flows as a share of GDP denominated both in current USD. All FDI series are *net flows*, accounting for the purchases and sales of domestic assets by foreigners in the corresponding year. The general definition of FDI is as investment that “reflects the objective of obtaining a

³ These sets of conditions are: (i) *The standard GMM conditions* of no second order autocorrelation in the error term: $E[pol_{i,t-s}(\varepsilon_{it} - \varepsilon_{i,t-1})] = 0$ for $s \geq 2$ and $t=3, \dots, T$; $E[y_{i,t-s}(\varepsilon_{it} - \varepsilon_{i,t-1})] = 0$ for $s \geq 2$ and $t=3, \dots, T$; $E[f_{i,t-s}^j(\varepsilon_{it} - \varepsilon_{i,t-1})] = 0$ for $s \geq 2$ and $t=3, \dots, T$, where y_{it} , f_{it}^j stand for the level of income and for FDI, respectively and where for instruments we use their past levels and differences. To instrument the FDI and the lagged output we used Stata's *GMM-style option*, and to instrument the remaining variables, corruption and elements of the x_{it} matrix, we used the *iv-style option*. (ii) *Additional conditions* of no correlation of the unobserved country-specific effect with their difference $E[(pol_{i,t-1} - pol_{i,t-2})(\mu_i + \varepsilon_{it})] = 0$; $E[(y_{i,t-1} - y_{i,t-2})(\mu_i + \varepsilon_{it})] = 0$; $E[(f_{i,t-1}^j - f_{i,t-2}^j)(\mu_i + \varepsilon_{it})] = 0$; (iii) The last condition allows using lagged first differences as instruments for levels.

⁴ A problem with System GMM estimator can arise if the instruments are too many, leading to overfitting of the model (Roodman, 2006). Unfortunately, there is little guidance in the literature to determine how many instruments are “too many” (Roodman 2006, Rudd 2000). A recommended rule of thumb by Roodman is that instruments should not outnumber individuals (or countries). We experimented with different numbers of lags in the instrumental matrix and results are largely consistent. We present here a set of results based on the minimum optimum lags, an approach that we selected to preserve the degrees of freedom.

lasting interest by a resident entity in one economy (“direct investor”) in an entity resident in an economy other than that of the investor (“direct investment enterprise”)” (OECD, *International direct investment database*, Metadata). This lasting interest implies the existence of a long-term relationship between the direct investor and the enterprise and a significant degree of influence on the management of the enterprise.

Direct investment involves both the initial transaction between the two entities and all subsequent capital transactions between them and among affiliated enterprises, both incorporated and unincorporated. A direct investment enterprise is defined as an incorporated or unincorporated enterprise in which a foreign investor owns 10 per cent or more of the ordinary shares or voting power of an incorporated enterprise or the equivalent of an unincorporated enterprise. A direct investment enterprise may be an incorporated enterprise - a subsidiary or associate company - or an unincorporated enterprise (branch). The data on sectoral FDI inflows to agriculture, mining, manufacturing, financial services and nonfinancial services FDI are compiled from *United Nations Conference on Trade and Development* (UNCTAD), *Organization for Economic Cooperation and Development* (OECD), *The Association of Southeast Asian Nations* (ASEAN), and individual national statistical agencies web sites.

The dependent variable, carbon dioxide (CO₂) emissions are from OECD and World Development Indicators (WDI). CO₂ emissions are defined as the emissions stemming from the burning of fossil fuels and the manufacture of cement. They include carbon dioxide produced during consumption of solid, liquid, and gas fuels and gas flaring.⁵ CO₂ emissions are measured in kilotons (kt).

Population density (people per sq. km of land area) is midyear population divided by land area in square kilometers. Population is based on the de facto definition of population, which counts all residents regardless of legal status or citizenship--except for refugees not permanently settled in the country of asylum, who are generally considered part of the population of their country of origin. Land area is a country's total area, excluding area under inland water bodies, national claims to continental shelf, and exclusive economic zones. In most cases the definition of inland water bodies includes major rivers and lakes.

⁵ CO₂ emissions accumulates in four kinds of carbon sinks: the atmosphere; the terrestrial biosphere (including freshwater systems and non-living organic material, such as soil carbon); the oceans- the largest sink (including dissolved inorganic carbon and living and non-living marine biota); and the sediments (including fossil fuels). Man-made CO₂ emissions are produced through fossil fuel burning and clearing forests for crop use. The carbon dioxide that is unabsorbed by natural sinks remains in the atmosphere, where it traps heat. The most vulnerable ecosystem is the ocean ecosystem, which become more acidic with rapid absorption of CO₂. It has been estimated that atmospheric CO₂ concentration has increased from 280ppmv to more than 380ppmv, since 1880, the sources being burnt coal, oil, and gas and that each doubling of atmospheric CO₂ concentration raises Earth’s mean temperature by 3°C (<http://climate.nasa.gov>). Rising temperatures have potential implications for ice sheet and glaciers melting and shifting seasonal and weather patterns.

Institutional variables are from the *International Country Risk Group* (ICRG). Following the FDI and pollution literature, we adopted the control of corruption as an independent variable and we did robustness check with law and order. Both measures are indexed from 0 to 6, 0 representing the countries with worst corruption and law and order practices, 6 representing countries with the best practices. Corruption includes financial corruption as well as favoritism, nepotism, etc. Law and order are assessed separately, each rated from 0 to 3 and involve the judicial system, and the crime rate.

Empirical Results

The idiosyncratic shocks to different sectors may overweigh the regional shocks and conceal the differences at the industry level, and may explain the reason behind inconclusive results in the literature. Our aim is to expose such effects if they exist. For this, we now turn to analyzing the industry spillover of sectoral FDI, given a set of control variables. We study the effects on the host country's pollution measures of sectoral and aggregate FDI, respectively. We examine the primary, secondary (manufacturing) and tertiary (services) sectors by further disaggregating the primary sector into agriculture and mining, and the tertiary sector into financial and nonfinancial sectors.

To control for heterogeneity caused by the level of development, we break down the data according to income distribution measures and examine the same effects in four income categories ranging from lowest to highest income countries following the World Bank specification: low-income countries, lower-middle-income countries, upper-middle-income countries, high-income countries. Since the number of countries in lower income countries is small, we combine the low-income with the lower-middle-income countries and report the combined results.

To give an overall view of the estimated regression equation and examine the EKC effect, Table 1 displays the full regression results for aggregate and sectoral FDI for all countries. The regression results for the full sample of countries are overall consistent with expected signs of coefficients. Evidence indicates a very strong persistence effect (1st row), underlying the cumulative nature of environmental degradation. The EKC hypothesis is supported by the data when inflows of investment are in agriculture and services (column 2 and 5). The institutional variable, control of corruption, comes in significantly and with the right sign in the regression with the total FDI (column 1), suggesting that less corrupt countries are also those implementing stricter measures against pollution. Indirect support for the pollution haven and direct support for the halo effect are found in the presence of manufacturing FDI and services FDI, respectively. As expected, the FDI-pollution estimate is often insignificant at the aggregate level, except in two industries. In manufacturing the positive and significant estimate suggests that flows into this industry degrade the environment in the host country. By contrast, the negative estimate in the services indicate that services FDI improve the environmental

conditions, supporting the halo Hypothesis. The breakdown with income distribution will help disentangle further these results.

In our analysis, we concentrate on the estimates of β_4 , the pollution effect of FDI flows, or the spillover effect. To save space, we summarize in one table its value across sectors and income distribution (Table 2). A negative value suggests that the data supports the Halo Effect hypothesis, while a positive sign is consistent with the Pollution Haven hypothesis, albeit this is not a direct test. In Table 3 we present the EKC estimates according to income distribution, which we obtain from the same regressions that give the results in Table 2.

(i) FDI impact on pollution

The effect of total FDI on CO2 pollution

The first row in Table 2 row reproduces the same results as Table 1, row 7. Column 2 also presents the breakdown of the impact of total FDI on the environment according to income categories. Although the aggregate impact of capital flows in the full sample is insignificant when all countries are taken together (1st cell), the analysis at different income levels reveals a striking regularity. Evidence shows a significant positive impact in low- and middle-income countries and a significant negative impact in high-income countries (first column), suggesting that FDI inflows deteriorate the environment in the relatively poorer countries, while they improve it in the wealthy countries. Results at the aggregate level thus support the Halo Effect hypothesis in rich countries and is consistent with the Pollution Haven hypothesis in poorer countries. How robust is this result across industries? Next, we turn to the sectoral level analysis.

The effect of primary sector FDI on CO2 pollution

FDI inflows to both agriculture and mining continue not to have a significant effect on air pollution in the full sample. (Table 1, first row, columns 3, 4). FDI inflows in agriculture mimic the results of total FDI. They worsen the CO2 conditions in middle-income countries, while improving it in the high-income countries where the halo effect continues to be relevant (column 3). In mining, by contrast, data supports the Halo Effect hypothesis more frequently (column 4). Lower middle-income countries and high-income countries benefit from FDI inflows into mining, where they presumably bring in “clean” technology, and there is weak evidence that it does it also in the poorer countries as well. However, upper middle-countries do not benefit from this technology where FDI inflows contribute to the air pollution. Thus, overall the FDI flows into the primary sector (columns 3 and 4) by and large parallel the total FDI results (column 2). In the lower middle-income countries the net effect of inflows to the primary sector cancels out (row 4), the upper-middle-income countries get dirtier technology (row 5), while high-income countries receive cleaner technology (last row).

The effect of manufacturing FDI on CO2 pollution

Most of the negative impact of capital inflows on air pollution in host countries is generated by manufacturing FDI (column 5). Inflow of foreign investment into this sector raises the pollution level significantly in the full sample (1st row). This result is traced back to low and lower-middle-income countries and high-income countries. Manufacturing FDI is the only type of investment flow that does not benefit the rich countries. Surprisingly, a strong halo effect is present in the upper middle-income countries.

The effect of tertiary sector FDI on CO2 pollution

In the full sample, the FDI in services benefits the environment (column 6, 1st row). This strong halo effect in the full sample can be traced back to a significant effect in the upper middle-income countries. Although there are other halo effects (poorest and richest economies), they are insignificant. No significant environmental deterioration due to service sector FDI inflows is depicted by the data. At the disaggregated industry level, however, positive spillovers are harder to detect. Only the lower middle-income countries appear to benefit from the financial FDI flows (column 7). The only significant impact of nonfinancial FDI is to increase pollution in poor economies, consisting of low and low-middle-income countries (last column). This result is consistent with the pollution haven effect of total FDI depicted in column 2. The insignificant estimate of services FDI in lower middle-income countries reflects the fact that the halo effect by financial FDI inflows is mitigated by the pollution haven effect of nonfinancial FDI.

Summary and discussion of findings on the impact of sectoral FDI on CO2 pollution and income distribution

Our findings can be interpreted in two ways: at the sectoral level and at the income distribution level depending on whether the reader examines the results vertically or horizontally. Examining the columns, at the industry level our results suggest that, foreign investment inflows into manufacturing and nonfinancial sectors are most likely to increase pollution and refute the Halo Effect hypothesis. Evidence supports the halo effect for FDI in services on the total sample. However, since we are able to partition the data according to income distribution, in this section we summarize our findings examining the rows.

At the aggregate level, we find that only high-income countries benefit from clean technology brought in by total FDI. By contrast, total FDI flows use dirty technology at all other income levels. When we consider sectoral flows, although results are more nuanced, overall they parallel the total FDI results. High-income countries still benefit from all type of FDI inflows, save for manufacturing, which are environmentally friendly and support the Halo Hypothesis. However, more FDI flowing into lower and low-

middle host countries have harmful effects, consistent with the Pollution Haven hypothesis.

More specifically, lower and lower middle-income countries' environment is degraded by FDI flowing in agriculture, manufacturing, and nonfinancial industries. However, FDI flowing into mining and financial services industries bring in clean technology. High-income countries' environment benefits significantly from FDI flowing in agriculture, and mining significantly and weakly from capital flowing into services. Only manufacturing FDI appears to worsen air pollution in these countries. This result stands in contrast to upper middle-income countries where the primary sector FDI flows into agriculture and mining degrade the environment, while those flowing into manufacturing and services improve it.

(ii) The Environmental Kuznets Curve Hypothesis

The hypothesis that pollution worsens during the initial growth process followed by an improvement as income rises is verified frequently and follows a surprising pattern (Table 3). The breadth of our findings reveals a more complex set of interactions between the level of development and pollution in a context of globalization and provides a compelling explanation for the ambiguity in the EKC literature. They show that the EKC hypothesis depends on the type of capital flows the countries receive and their level of development, and thus highlights the importance of accounting for heterogeneity, regional effects and dynamics in the data.

As indicated in Table 1, in the full sample the EKC is strongly present in countries receiving agriculture and services FDI. The same pattern is repeated in low-income and lower middle-income countries, and in each subsector of the services industries. In other words, the EKC is confirmed in relatively poor countries, especially those receiving FDI flows in agriculture, financial and nonfinancial services. Interestingly, upper middle-income countries exhibit the EKC only when FDI flows to mining and manufacturing. Another intriguing finding of our study is to show that EKC is mostly inexistent in high-income countries, except when they host FDI in manufacturing. The traditional EKC results thus still hold at an early level of development, for most types of capital inflows. As countries become wealthier, EKC is supported if countries allow capital inflows in traditionally dirty industries, such as mining and manufacturing.

(iii) Additional tests: alternative measures of pollution and institutional variables

In this and the next subsections we discuss some additional results we obtained by using different data and controlling for different factors. We do not display the results for sake of preserving space; however they are available from the authors.

Does FDI inflows change air pollution caused by particles other than CO₂, such as SO₂ (sulfur dioxide), NO₂ (nitrogen dioxide) and CO (carbon monoxide)? Although

most of the discussion about man-made climate change centers around the impact of CO₂, the other particles are greenhouse gases directly generated by industrial pollutants. Since data are available only for the OECD countries, we were able to conduct the analysis only at the sectoral level and not income levels. We found that the halo effect is visible in services FDI also with SO₂ and NO₂ pollutants, especially in nonfinancial flows, whereas financial FDI contributes to a decline in NO₂. In contrast, data reflects a bleak picture for the CO pollution. Evidence suggests that among OECD countries, FDI flows into mining and services raises the levels of CO significantly in host countries, raising a broader concern on FDI-induced air pollution.

We tried alternative measures of institutional variables. One such measure from the same data source is law and order. Results were largely consistent but with fewer significant coefficients. Since this is a variable more broadly defined and less precise than the corruption measure we used, we thus chose to keep the latter.

We also wanted to examine if the Kyoto Protocol signed in 1997 by 191 countries and entered into force in 2005 had any impact on the estimates and parameter stability. If the protocol had a significant impact, possible changes we expected were an increase in the production costs of polluting industries, therefore a decline in the positive coefficients, and/or a decrease in the costs of clean industries and a rise in the negative coefficients. To our surprise, our results remained unchanged. This may mean either that the protocol has been ineffective, or it did not have time to work through the estimated coefficients.

(iv) Other estimates of the model

Here we briefly review the remaining parameter estimates in the income categories. We find that the persistence of pollution is highly robust to income distribution. Control of corruption is significant reduces pollution in upper middle-income countries that are host to FDI in mining and all services sectors, and in high-income countries that are host to FDI in manufacturing and in both services subsectors. Control of corruption in general has no effect on environmental degradation in poorer countries. Population density increases pollution in lower middle-income countries receiving manufacturing and agricultural FDI, but it has a negative impact on pollution in high-income countries and in high middle-income countries.

Conclusion

In this study we examine the relation between globalization as represented by inflows of capital and environmental degradation as represented by the CO₂ air pollution. Our study tests the Halo Effect hypothesis, which argues that foreign direct investment is beneficial to the host country because by bringing in clean technology and know-how, it improves the environmental standards. This view stands in contrast to the Pollution

Haven hypothesis, which states that tight environmental regulations in developed countries shift dirty industries to poorer countries with lax policies.

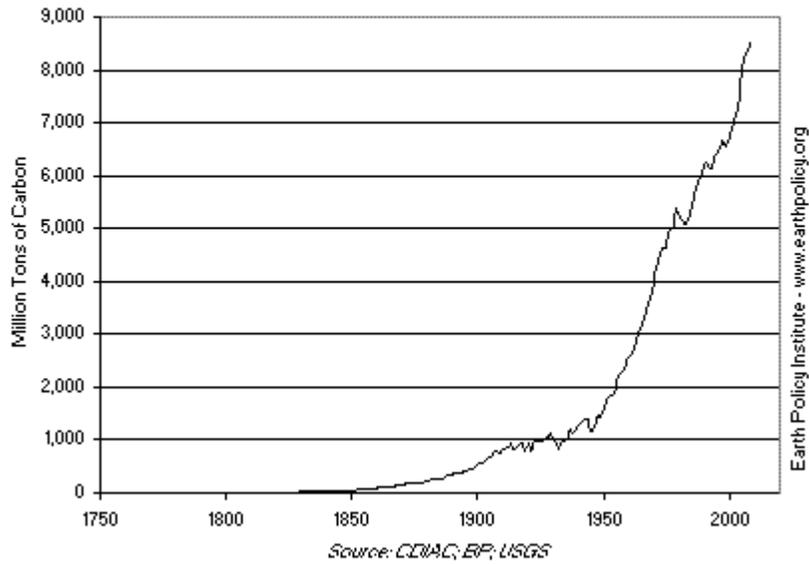

By using a methodology that allows us to exploit a rich data set, we examine the impact of sectoral direct investment flows on air pollution. We find that results vary critically according to the type of capital flow and income category. Foreign investment flows into manufacturing tend to support the pollution haven argument, while those flowing into services support the Halo Effect hypothesis. In general, foreign investment flowing in poorer countries has more harmful effects on environment, while those flowing to richer countries have a beneficial effect and support a halo effect. However, when air pollution is measured by a different pollutant measure more industrialized countries may be adversely affected.

Furthermore, in our analysis, we shed light on the inconclusive results of the EKC (environmental Kuznets curve) literature, which examines the inverse U-shaped relation between pollution and the income in a country. We show that the traditional EKC results hold at an early level of development for most types of capital inflows. As countries become wealthier, EKC is supported if countries allow capital inflows in traditionally dirty industries, such as mining and manufacturing

Our results thus suggest that studies relying simply on aggregate data or on firm level data to analyze the relation between the environment and globalization miss the subtle characteristics of the data due to complex interaction of sectoral flows and the environment. These studies can lead to wrong or inconclusive inference and thus to misleading policy prescriptions, with a long lasting impact.
