Abstract

In this paper, we propose a statistical model of multi-product exporters to characterize the null hypothesis of random product size distribution. It serves as a benchmark to test the empirical facts and predictions of theoretical models. We show that the statistical model accounts for some well-documented differences between large and small scope exporters that are consistent with many theoretical models, including the ones featuring core-competencies, productivity differences, and economies of scope.
1 Introduction

Across the world, multi-product firms dominate international trade flows. Famously, Bernard et al. (2010) document that multi-product firms account for 98% of the U.S. manufacturing exports. In other countries multi-product exporters have been shown to play an equally important role. In light of this empirical importance, researchers are interested in understanding why multi-product exporters arise and how they respond to changes in the international trade environment. In recent years there has been some progress in answering these questions both on the empirical and theoretical fronts. For example, Allanson and Montagna (2005), Nocke and Yeaple (2015), Bernard et al. (2011), Eckel and Neary (2010), Dhyne et al. (2017), Arkolakis et al. (2020), and Bernard et al. (2010) are just few of the papers that explore how to model multi-product exporters and their response to changes in the international trade environment. These papers feature product level heterogeneity either on cost or demand side but also emphasize firm level differences in productivity, brand-effects, as well as differences in the costs of introducing new products. In part, these views on multi-product exporters are rooted in a number of empirical regularities documented using the newly available firm-product level data.

In this paper we take a step away from the behavioral models of multi-product exporters, and instead focus on the empirical regularities that underpinned those models. We aim to understand which ones are informative
about the economic forces that drive multi-product exporters and which ones arise as a result of randomness and aggregation. To this end we develop a statistical model where pure chance drives exporter outcomes and allows us to characterize the null hypothesis of the product size distribution. The statistical model provides a benchmark for data patterns and economic hypotheses such as core competencies, economies of scope, and productivity differences in multi-product exporters among others.

The original motivation for this research question comes from the work of Ellison and Glaeser (1997), who highlight that data patterns and predictions of economic models should be compared to patterns that would arise if the outcomes of interest were randomly distributed rather than to a uniform pattern or an absence of a pattern.

This paper is also close in spirit to the work of Armenter and Koren (2014) who highlight that many facts about the extensive margin of trade are consistent with a surprisingly large class of models because of the sparse nature of trade data. In relation to multi-product firms they show that the “bins-and-balls” model quantitatively reproduces the frequency of single product exporters at a destination but not the right tail of the exporters’ scope distribution.

In this paper we take exporter scope as given and focus on the differences between large and small scope exporters on the intensive margin. Our key insight is that many empirical regularities about multi-product exporters involve order statistics. Comparing large and small scope exporters in terms
of their best/least selling products, correlation between product rankings across markets are just few examples. We show that various robust patterns arise in order statistics calculated for different number of products even when the underlying data is randomly distributed. Hence some (but not all) of the well-documented regularities about multi-product are consistent with a wide variety of models including the ones where pure random chance drives exporter sales.

The rest of the introduction is split into two sub-sections. First, we discuss the differences between large and small scope exporters at a single destination. These differences have motivated several explanations as to why multi-product exporters dominate international trade including firm-specific productivity, brand-effects and core-competencies. In the second, we discuss empirical regularities about multi-product exporters in multi-destination setting. We address empirical regularities that document how multi-product exporters respond to differences in competitive environments across destinations and the extent to which correlation between global and local product rankings reflects firm core-competencies.

1.1 Single-destination Regularities

Consider the following three facts that have been documented across a number of data-sets and countries:

1. Arkolakis et al. (2020) and Timoshenko (2015) document these patterns for Brazil; Bernard et al. (2011) and Bernard et al. (2010) document them for the U.S. In this paper we document them for Chinese exporters to the U.S.
1. Large scope exporters sell more in their best selling products than small scope exporters.

2. Large scope exporters sell less in their least selling products than small scope exporters.

3. Average sales per product are non-monotone with scope.

The first fact is consistent with many models of multi-product exporters where a single firm attribute, usually firm productivity, drives both scope (the ability to produce many products) and scale (the ability to produce at scale due to lower marginal cost). Examples include Bernard et al. (2011), Bernard et al. (2010), and Arkolakis et al. (2020). To set ideas straight, consider a Melitz’s style model where firms face random product-specific shocks (on the cost or demand side) and a single firm productivity which translates into a marginal cost parameter common across all of its products. All else constant, lower marginal cost implies higher product sales and higher variable profits, which encourage high productivity firms to export more products. While not all products exported by high productivity exporters sell in large amounts due to product-specific shocks, the Melitz’s style model implies a positive correlation between sales and scope. Indeed, the fact that large scope exporters sell more in their top-selling products than do small scope exporters is often used to motivate models where firm productivity drives both scope and scale.

The second fact is consistent with models where a product introduction
fee (also known as a product specific market access cost or a fixed cost of exporting\textsuperscript{2} decreases with exporter scope as in \textcite{Arkolakis2020} and \textcite{Timoshenko2015}. A multi-product firm expands its scope as long as the profit from the marginal product exceeds the product introduction fee. Firms that face lower product introduction fees are able to profitably export less efficient products that sell in smaller amounts (\textcite{QiuZhou2013}). To the extent that sales of the least selling product reflect the exporter’s marginal product, the Fact 2 is consistent with a model where product introduction fees decrease with scope. With large scope exporters selling some of their products in extraordinarily large amounts, and other in tiny amounts, average sales per product are then indeterminate as a function of scope due to composition effects (Fact 3).

In this paper, we show that the facts above, while consistent with several models of multi-product exporters, can also arise due to random chance alone. In other words, there is no evidence in the data to support that large scope exporters sell their best (least) selling products in larger (smaller) amounts than small scope exporters beyond what we would expect if sales were randomly distributed across firms and products.

To see the intuition, consider a two product firm and a ten product firm. Suppose that sales per product are just iid draws from the same distribution across firms and products, then the expected value of the maximum of ten

\textsuperscript{2}In a static Melitz’s style model a product introduction fee and the market access cost are equivalent to the fixed cost of exporting a product.

\textsuperscript{3}\textcite{Arkolakis2020} refer to the product introduction fee as a market access cost.
products is higher than the maximum of two products. The reverse is true for the minimum. Hence larger scope exporters may have higher sales in their best selling products and lower in their least selling products relative to the smaller scope exporters simply because we aggregate data over a different number of products.

Formally, Facts 1 and 2 above are examples of order statistics, i.e., average sales across products at a given rank. Order statistics are systematically related to the number of products for which they are calculated. So mean sales of the best selling product increase with exporter scope while mean sales of the least selling product decrease with exporter scope even if all exporters drew sales from the same distribution. If more productive firms select into exporting more products then we should see that large scope exporters not only sell more than small scope exporters in their top-ranked products, but also that they sell more than if their sales came from the same distribution as single product exporters. Similarly, if large scope exporters faced lower product introduction costs, they would sell less in their least selling products compared to the small scope exporters, and less than if their sales were driven by chance.

While in theory chance and aggregation can generate the observed differences between large and small scope exporters, whether they are sufficient to replicate these quantitatively is an empirical question. To answer it we formalize chance in an intentionally stark statistical model of multi-product exporters. In the model the number of exported products per firm is treated
as exogenous, and product revenues are iid realizations from some distribution $F()$.

In our empirical implementation $F()$ is either Pareto or log normal. We show that when $F()$ is log-normal, the statistical model replicates Facts 1 and 2 (as well as other order statistics) remarkably well. When $F()$ is Pareto, the statistical model also replicates Fact 1 and Fact 2, although it tends to overestimate how quickly sales at a given rank increase/decrease with scope. The poor empirical performance of the Pareto stems from its failure to approximate the left tail of the sales distribution and echoes the findings of Head et al. (2014), Bee and Schiavo (2018), and Fernandes et al. (2015).

The fact that the statistical model can replicate Fact 1 highlights that one should be careful not to interpret it as evidence that large scope exporters are more productive. For example, in the data, Chinese exporters to the US with five or more products sell almost eight times as much as single product exporters in their top selling products.\(^4\) Our results show that if large scope exporters drew sales from the same distribution as single product exporters the difference between how much large and small scope exporters sell in their best selling products would be even greater. Similarly, Fact 2 on its own should not be interpreted as evidence of product introduction fees decreasing with scope. Variation in average sales per product, Fact 3, on the other hand cannot be replicated by the statistical model and provides a useful metric to compare large and small scope exporters.

\(^4\)See Table 1.
Put another way, our results suggest that firm scope is a sufficient statistic for the differences between large and small scope exporters on the intensive margin. Variance in firm-product shocks is enough to generate the observed differences in sales at rank between large and small scope exporters. So, a model that can successfully replicate firm scope will also replicate observed differences between large and small scope exporters. In this regard, our work speaks to the literature on the role of firm productivity and product introduction costs in determining the scope and scale of multi-product firms. Our results echo Macedoni and Xu (2020), who showed that scope and measured productivity are only imperfectly correlated, and that variation in the ability to introduce new products plays a relatively more important role in driving exporter scope. We contribute to this debate by highlighting that the notion of firm productivity being a key driver of both scope and scale should be treated with caution because the differences between large and small scope exporters seemingly caused by firm productivity can arise due to chance.

1.2 Multi-destination Regularities

After considering documented differences between large and small scope exporters at a single destination, we extend the statistical model to the multi-destination setup to see if it can reproduce other empirical facts that rely on order statistics. We focus on two popular regularities. First, is the observation that in more competitive markets multi-product exporters tend to have their sales more concentrated in their core products. A measure of
sales concentration that is often used in this context is the ratio of sales between the best selling and the second best selling product. We show that this measure produces biased results. (biased towards what?). Second, we consider correlation between global and local product rankings that has been used to capture core-competencies among multi-product firms. Our results show that core-competencies play an important role in driving correlation between global and local product rankings. Yet this correlation is far from zero when sales are randomly distributed across firms and products. Therefore one should compare the correlation in the data to the correlation that would arise if product sales were randomly distributed.

We first address the ratio of sales between the best selling and the second best selling product as a measure of sales concentration. One reason behind its widespread use is that some theoretical models predict it as a function of variables that proxy market competitiveness at a destination. The best-known example of this is the seminal work by Mayer et al. (2014). They show that when product demand is linear, and firms face variable mark-ups, multi-product firms adjust their product mix by reallocating resources across products at a destination. Firms expand production of their core (low cost and high mark-up) varieties at the expense of the peripheral ones, thus increasing the concentration in the core (top selling) varieties. To test this prediction, Mayer et al. (2014) regress the log-ratio of sales between the best selling and the second best selling product on the destination market size, market supply potential, bilateral trade costs and other proxies of market
competitiveness. Using the estimated impact of market size on the log-ratio together with their theoretical model they calculate that the within-firm resource reallocation contributes a nontrivial 19% to aggregate productivity in response to trade liberalization.\footnote{Mayer et al. (2014) also use a global ratio and provide robustness checks in the appendix where they show that concentration increase is captured by the Theil and Herfindahl indices as well. However, their discussion of the economic implications and the main results in the paper are based on the log-ratio measure of concentration which is vulnerable to the bias due to the unaccounted number of products.}

Our multi-destination extension of the statistical model highlights that a regression where log-ratio is the dependent variable, as in Mayer et al. (2014), may produce biased results. This is because unless sales are distributed Pareto, the log-ratio, which is the function of two order statistics, systematically depends on the number of products the firm exports. If sales are log-normally distributed, for example, the expected value of the ratio decreases with the number of products a firm exports to a destination. So, if firms export fewer products to a more distant destination or one with a higher foreign supply potential, the ratio would be higher there even if sales were randomly distributed as is in our statistical model. Our quantitative results show that the regression coefficient on the market size underestimates the effect of market size on changes in the product mix. On the other hand, market supply potential or bilateral distance which are associated with smaller exporter scope will have coefficients biased upwards. Intuitively, the impact of factors that are associated with firms exporting more products to a destination will be underestimated, while the impact of factors associated
with fewer exporters will be overestimated. Our results show that the bias indeed exists and thus suggest that the within-firm resource reallocation may contribute more than the 19% to aggregate productivity that Mayer et al. (2014) calibrated based on the estimated coefficient of the market size.

Second, using the multi-destination model we address the correlation between global and local product rankings which is frequently used to evaluate the empirical relevance of core-competencies. Core competence refers to the idea, initially proposed by Eckel and Neary (2010), that firms have a lower marginal cost in their core product than in peripheral products. This implies that multi-product exporters will tend to export their core products to many destinations and that the core products will be at the top of the product ladder across these destinations. To measure this effect researchers calculate correlation between local and global product rankings. We show that correlation between the global and local rankings is sizable even when product sales are randomly distributed. Moreover it systematically increases with the number of products the firms export and decreases with the number of destinations. When we compare the correlation that we observe in the data to the correlation generated by the statistical model we find that randomness alone is not enough to explain the correlation observed in the data and our results support the empirical relevance of the core-competencies.

In this paper we contribute to the empirical literature on multi-product exporters by highlighting that data regularities which involve order statistics, such as best/least selling products, systematically vary with the number
of products for which they are calculated. Our insight is that instead of comparing sales at rank between exporters of different scope, one should compare sales that are observed to those that would arise if firms drew sales from the same distribution. Some of the patterns used to characterize multi-product exporters turn out to be consistent with a wide variety of models, including the statistical model where ex-post differences between large and small scope exporters arise because they involve aggregating firm-product level outcomes driven by pure chance over a different number of products to the firm level.

One should, however, be careful not to interpret our results as evidence against behavioral models of multi-product exporters that feature firm productivity or resource reallocation in response to trade shocks. Beyond the well-documented patterns that we focus on here, there is work that provides direct evidence on these channels. For example, Dhingra (2013) find that firms invest in cost-cutting technology for their core products and drop peripheral products in response to trade liberalization in Malaysia. Dhyne et al. (2017) use a novel multi-product firm production function estimation approach to estimate technical efficiencies of individual products. They find that firms are more efficient at producing core products and respond to competition by focusing on them. Rather, one should see our results as insights into which data moments are informative about multi-product firm behavior and which should be considered with extra care.

The paper proceeds as follows. Section 2 lays out the statistical model and
discusses the intuition behind it. Section 3 presents the calibrated results, Section 4 extends the baseline model to multi-country set-up and Section 5 concludes.

2 Statistical Model of Multi-product Exporters

We now present a statistical model of multi-product exporter outcomes. We begin with a single destination version and later extend it to the multi-destination set-up in Section 4.

A multi-product exporter indexed by $f$ is a collection of products $K$ that a firm exports in a given year. Products within a firm are indexed by $k \in \{1, ..., K\}$. The number of products a firm exports ($K$) is treated as exogenous and in empirical applications will be taken from the data. Product sales $S_{fk}$ are iid draws from some continuous distribution $F()$ with a non-negative support.

In this stark set-up, any differences between large and small scope exporters on the intensive margin are driven by aggregating random draws over the different number of exported products to the firm level. So by comparing the observed patterns and model predictions to the predictions of the statistical model, we will be able to separate the data patterns that are genuinely informative about the economic forces driving the intensive margin from the ones that reflect randomness and aggregation.

This statistical model has four main predictions about the within firm
product size distribution. When products within a firm are ranked by their contribution to total sales from the best selling to the least selling the model predicts:

**Prediction 1.** Bigger scope exporters sell more in their best selling products than smaller scope exporters.

**Prediction 2.** Bigger scope exporters sell less in the lowest ranked products than smaller scope exporters.

In the model, the large scope exporters get to make more sales draws (one for each product) than smaller scope ones. As long as the draws are iid across firms and products, the maximum of the larger number of draws is bigger than the maximum of the smaller number of draws. The reverse is true for the minimum. In Section 3 we demonstrate that both predictions are independent from the assumptions about the distribution and find strong support in the data.

While in the statistical model the two predictions arise due to randomness and aggregation, models where firm productivity and product introduction fees drive exporter scope and scale would generate similar predictions (at least qualitatively). Prediction 1 is consistent with the models of multi-product firms where firm productivity determines both scope and scale. Faced with random demand shocks as in Bernard et al. (2011) high productivity firms have higher expected profits from a new product and so select into more

---

6 These patterns are also documented in Arkolakis et al. (2020), Timoshenko (2015), Bernard et al. (2011) and Bernard et al. (2010).
products. By virtue of higher productivity large scope exporters sell their best selling products in larger amounts than their small scope counterparts.

Similarly, Prediction 1 is consistent core-competencies multi-product firm models where firms are endowed with a core-competency in one of the products and as they expand into products further from the core product the marginal cost of the product increases. The marginal cost of the core product is determined by a firm level productivity so more productive firms can introduce more peripheral products. Thus large scope exporters will sell more in their top-selling products than small scope exporters. It’s worth noting that multi-destination extensions of the core-competencies model imply a positive correlation between local and global product rankings. Something that the extension of the statistical model to the multi-country set up falls short of replicating.

Prediction 2 is consistent with a model where a product introduction fee decreases with exporter scope. Exporters choose their scope by equating marginal profit from a product to the product introduction fee. When product introduction fees decrease with scope larger scope exporter are able to profitably sell less efficient products. Large scope exporters will then sell their least selling products in smaller amounts than the smaller scope exporters.

Prediction 3. Average sales per product are constant with scope.

Evidence on the relationship between average sales per product and firm scope is mixed. As a rule, average sales per product is not monotone with scope. See Bernard et al. (2011), Arkolakis et al. (2020). Many models of
multi-product firms avoid making predictions about average sales per product because they reflect composition effects (i.e. large scope exporters sell their products in both extraordinarily large and small amounts). Yet, our results suggest that variation of average sales with scope cannot be replicated with randomness alone and so is a useful moment to differentiate between alternative models of multi-product exporters.

**Prediction 4.** *The expected value of the log ratio between sales of the best and the second best selling product is constant with scope when sales are distributed Pareto and decreases monotonically with scope when sales follow log-normal, Weibull or exponential distributions.*

In Appendix A, we present analytical proofs for Pareto, Weibull and exponential distributions. We use numerical integration to establish the result for the log-normal distribution.

The log ratio of the best selling to the second best selling product is often used as a measure of sales concentration within a firm. It is thought to capture how firms respond to changes in competition by adjusting quantities and prices across the product range. We highlight that there is also a mechanical relationship between the number of products a firm exports to a destination and the log-ratio, unless sales are Pareto distributed. This matters because within-firm reallocation of resources usually coincides with adjustments on the extensive margin. Faced with tougher competition, firms drop products which would have the effect of increasing the ratio even if firms
did not respond optimally on the intensive margin. Hence, the effect of market competitiveness measures on the skewness of sales measured using the ratio is likely to be biased. We explore this issue in detail when we discuss the multi-destination extension of the model in Section 4.

3 Empirical Test of the Model

In this section, we test the predictions of the statistical model. When we compare predictions of the statistical model to the data we find that large scope exporters sell no more in their top selling products than if their sales were random. In fact they sell less in their top selling products than if they drew their sales from the same distribution as single product exporters (Prediction 1). Similarly, once we take into account randomness and aggregation, large scope exporters sell no less than small scope exporters in their least selling products (Prediction 2). This is in contrast to the conclusions one may make by comparing sales at rank between large and small scope exporters. However, the statistical model is unable to replicate the variation in average sales per product (Prediction 3). In terms of the log ratio of sales between the best selling and the second best selling product, the model replicates the rate at which the ratio decreases with scope but underestimates average ratio at a given scope (Prediction 4). In Section 4 we address the implications of Prediction 4 for measuring the exporters’ response to changes in the competitive environment using a multi-country version of the statistical
model.

3.1 Estimation Details

To test the predictions of the statistical model we use data on firm-product sales available at the HS-6 level for Chinese exporters to the US in 2003. In Table 1 we verify the multi-product exporter facts documented for other countries in the Chinese data. The table splits the sample based on the number of products each firm exported and for each group reports average total exporter sales, as well as average sales of the best and least selling products. While small in number, large scope exporters dominate the export market in terms of their sales. Single product exporters, for example, account for 41 percent of exporters while exporters with five or more products account for only twenty percent. Yet, exporters with five or more products sell ten times as much as single product exporters. Exporters with five or more products sell almost eight times as much as single product exporters in their best selling products. They also sell much less in their least selling products than small scope exporters.

To test the predictions of the statistical model we first estimate the distribution of product sales \( F() \) and then use the estimated distribution to simulate the moments about which the model makes predictions. We then compare the simulated moments to the data and infer which patterns can be explained with the statistical model alone, and which ones are informative about the economic forces that produced the data.

The table splits the sample of exporters from China to the US according to the number of products that they exported in 2003 into exporters with 1,2,3-4, and 5 or more products. For each group it reports the share of exporters, mean total exporter sales and mean sales of the best and least selling products for each group. Sales are in thousands of USD.

In the data, firm-product sales systematically vary with product categories (at the HS6 group level). To take this into account we adjust annual sales data (used in Table 1) relative to the average product sales across all Chinese exporters to the US selling in the same product category.

We use the log-normal and Pareto distributions to approximate the empirical distribution of product sales $F()$. To estimate the parameters of each distribution we use either the Maximum Likelihood (ML) or the Simulated Method of Moments (SMM) approach. With the latter we target sales at rank statistics conditional on exporter scope. (The targeted moments are in Figures 2(a) and 2(b).) The ML approach is a more stringent test of the model since we do not directly target the moments we want to explain in the estimation. If the distribution $F()$ accurately describes the data on sales, both approaches should yield similar results. This is indeed the case for the log-normal distribution but not for the Pareto.
3.1.1 Log-normal Distribution

If sales $S_{fk}$ follow the log-normal distribution with the location and shape parameters $\mu$ and variance $\tau$, the natural logarithm of sales $\ln(S_{fk})$ follows the normal distribution with mean $\mu$ and variance $\tau$. The top panel of Table 2 reports the ML and SMM estimates for the shape and location parameters of the normal distribution fitted to the data on the natural logarithm of sales. The bootstrapped standard errors are in parentheses and indicate that estimates are statistically significant. Both the ML and SMM approaches yield very similar results and both closely track the actual distribution of the log sales in Figure 1. The ML approach yields only slightly thicker tails due to higher estimated variance. This is what one would expect if the estimated theoretical distribution approximates the empirical one reasonably well.

The predictions of the statistical model that we have set out to test involve order statistics conditional on scope, i.e., best, second best, and least selling products. The model will only be able to quantitatively match the data if it can replicate the correlation between order statistics and exporter scope that we observe in the data. In Figure 2(a) each panel looks at average sales at rank for firms with the same scope. In panel three, for example, for each firm that exported three products in 2003 we rank the products by their contribution to its total sales at the destination. So the product with the highest contribution is assigned rank one. Along with average sales at rank and scope from the data we also report the corresponding moments simulated from the statistical model. The moments simulated at the ML
and SMM estimates track the actual data remarkably well.

3.1.2 Pareto Distribution

If sales \( S_{fk} \) are Pareto distributed with a location parameter \( \alpha \) and shape parameter \( \nu \) then \( \ln(S_{fk}) - \ln(\alpha) \) is distributed exponentially with the rate parameter \( \nu \). To estimate the parameters of the Pareto distribution with the Maximum Likelihood we first calibrate the location parameter \( \alpha \) to the smallest sale value in the sample, \( \hat{\alpha} = \min(S_{fk}) \), and then estimate the rate parameter \( \nu \) by fitting the exponential distribution to data on \( \ln(S_{fk}) - \ln(\hat{\alpha}) \).
Figure 1 – The figure shows the estimated density of log-sales under the hypothesis that sales are Pareto or log-normally distributed using the Maximum Likelihood and the Simulated Method of Moments approaches against the empirical distribution of log-sales.
Figure 2 – Each panel looks at average sales at rank for firms with the same scope (indicated at the top of each panel). The x-axis reports the rank of the product and the y-axis reports average sales of products conditional on product rank and exporter scope. Product rank is assigned for each product based on its contribution to total sales of the exporter at the destination. A product with the highest share of sales has rank 1. The last panel in Figures 2(a) and 2(b) shows sales at rank for firms with 6 or more products. The rank “6+” on the x-axis corresponds to the least selling product, i.e., the y-axis shows average sales in the least selling product for exporters with 6 or more products.

(a) Sales distributed log-normally.
SMM series corresponds to log-Normal distribution with mean $-1.6$ and variance $2.12$ estimated by the SMM approach. MLE series corresponds to log-Normal distribution with mean $-1.6$ and variance $2.64$ estimated by the ML approach.

(b) Sales distributed Pareto.
SMM series corresponds to Pareto with location parameter $0.000059$ and shape parameter $0.074$ estimated by the SMM approach. MLE series corresponds to Pareto with location parameter $0.000003$ and shape parameter $0.13$ estimated by the ML approach.
With the SMM approach we jointly estimate $\alpha$ along with $\nu$ by targeting mean sales conditional on rank and scope. The second panel of Table 2 reports the estimates. The SMM and ML estimates are quite different, which indicates that the distribution is likely to be misspecified. Figure 1 compares the estimated exponential distribution with the actual distribution of log-sales and the fitted normal density. Regardless of how parameters are estimated, Pareto performs poorly in replicating the sales distribution. The poor empirical performance of the Pareto stems from its failure to approximate the left tail of the sales distribution and echoes the findings of Head et al. (2014), Bee and Schiavo (2018), and Fernandes et al. (2015) who show that the log-normal distribution provides a better fit for the entire distribution of the exporter sales than the Pareto. Similarly, in Figure 2(b) the order statistics simulated from the statistical model with sales distributed Pareto fit the data poorly. Whether we estimate the parameters of the distribution with ML or SMM, the statistical model tends to overestimate how quickly sales at rank decrease with rank at a given scope.

In the following subsection we show that the statistical model with sales-distributed log-normally quantitatively replicates the observed data patterns. If sales are distributed Pareto the statistical model predicts much bigger differences between the large and small scope exporters than we observe in the data.
3.2 Test of the Statistical Model

In this section, we compare the predictions of the statistical model to the patterns in the data and thus identify when differences between the large and small scope exporters arise due to aggregation and when these differences call for an economic explanation.

3.2.1 Prediction 1

In Figures 3(a) and 3(b) we address Prediction 1, i.e. large scope exporters sell more in their best selling products than small scope exporters. In Figure 3(a), we compare the mean sales of the best selling products as a function of exporter scope in the data to those simulated from the statistical model assuming sales are distributed log-normally. The parameters of the log-normal distribution were estimated using either the ML or the SMM approach and are given in the top panel of Table 2. In the data, exporters with six or more products sell more than six times as much as single product exporters in their top-selling products. If instead, we compare the data to the predictions of the model we see that large scope exporters sell no more in their top-selling product than the statistical model predicts. The pattern simulated from the SMM estimates tracks the data closely\textsuperscript{7} and shows that the differences between the large and small scope exporters can arise even if firm-product sales are iid random draws. The pattern simulated from the ML estimates, in

\textsuperscript{7}This is not surprising since we have explicitly targeted order statistics conditional on the firm scope.
fact, predicts that large scope exporters should sell more in their top-ranked products than we observe in the data.

Comparing the predictions of the statistical model from the ML and SMM estimates highlights that differences between large and small scope exporters are driven by variance in sales. The SMM and ML approaches produce identical location parameter estimates, but the latter yields a bigger shape parameter $\sigma$, which implies a greater variance of sales. This illustrates that a higher variance of sales translates into bigger differences between large and small scope exporters.

Figure 3(b) is analogous to Figure 3(a) with the difference that the distribution of the firm-product sales $F(\cdot)$ is set to be Pareto with parameter estimates given in the second panel of Table 2. While the moments simulated from the Pareto distribution poorly track the data, it's worth pointing out that the model still predicts that large scope exporters sell more in their top-selling products than small scope exporters. In fact, Pareto predicts much bigger differences between large and small scope exporters than we actually observe. The patterns simulated from the log-normal and Pareto both illustrate that one should be careful not to interpret the observation that large scope exporters sell more in their top-selling products than small scope exporters as evidence of large scope exporters being more productive.

To highlight this point further, we ask how much more large scope exporters would sell in their best selling products if their sales came from the same distribution as single scope exporters. To this end, using the ML es-
Figure 3 – Average sales in the top-selling product for exporters of different scope.

(a) Sales distributed log-normally. MLE series corresponds to the log-normal distribution with a mean of -1.6 and variance 2.12, and SMM series corresponds to the log-normal distribution with a mean of -1.6 and variance 2.62.

(b) Sales distributed Pareto. SMM series corresponds to Pareto with location parameter 0.000059 and shape parameter 0.074 estimated by the SMM approach. MLE series corresponds to Pareto with location parameter 0.000003 and shape parameter 0.13 estimated with the ML approach.
Figure 4 – In the simulation, sales are distributed log-normally. The location and shape parameters are estimated from the data on single product exporters only.

(b) Ratio of the mean best selling product in the data to the simulated analogue from the statistical model conditional on exporter scope.
imator we estimate the location and scale parameters of the log-normal
distribution from the data on single-product exporters only. The location
and scale parameters are estimated to be -1.73 and 2.61, respectively. The
details are in the bottom panel of Table 2. In Figure 4(a) we compare the
simulated mean sales of the best selling products conditional on exporter
scope to the data. Mean sales of the single product exporters in the data
and the simulation are virtually identical by construction. The statistical
model predicts that if larger scope exporters drew sales from the same distri-
bution as single product exporters, they would sell more in their top selling
products than we observe in the data.

To understand just how much more, in Figure 4(b) we plot the ratio of
the simulated moments to the data moments. For single product exporters
this ratio is one by construction but as scope increases the ratio decreases to
0.6 for exporters with six and more products. This means that if exporters
with six and more products drew their sales from the same distribution as
the single product exporters, they would sell almost 60 percent more in their
the top-selling products than we observe in the data.\footnote{To be exact, the ratio between the observed and simulated average sales in the top-
selling product for exporters with six or more products is 0.64. This implies that the
difference between the simulated and observed sales constitutes 56 percent of the observed
sales.}

3.2.2 Prediction 2

Figures 5(a) and 5(b) look into the mean sales of the least selling products
by exporter scope to address Prediction 2. The two figures compare data
to the moments simulated from the statistical model under the assumption that sales are log-normally \(^{(5(a))}\) or Pareto \(^{(5(b))}\) distributed. In \(^{(5(a))}\) the moments based on the SMM estimates narrowly track the data and predict that large scope exporters sell only slightly more in their least selling products compared to the data. The ML estimates, on the other hand, predict that large scope exporters sell less in their least selling products relative to the data. Although Pareto in Figure \(^{(5(b))}\) falls short of quantitatively replicating the data quite dramatically, it too predicts that average sales of the least selling product decrease with scope. This suggests the observation that large scope exporters sell less in their least selling products than the small scope exporters can arise because we aggregate sales across different number of products and should not be viewed as evidence that product introduction fees decrease with scope.

In Figure \(^{(6(a))}\) we compare what we observe exporters to sell in their least selling products conditional on exporter scope to what they would sell if their sales were drawn from the log-normal distribution fitted to the data on single product exporters only. (For the estimated parameters of the distribution see the bottom panel of Table \(^{2}\)). The figure shows that the differences between how much large and small scope exporters sell in their least selling products would have been even bigger if large scope exporters drew sales from the single product distribution. Figure \(^{(6(b))}\) shows the ratio of the simulated and actual mean sales of the least selling products. In percentage terms this implies that exporters with six or more products would sell 11 percent less
Figure 5 – Average sales of the least selling products by exporter scope

(a) Sales distributed log-normally. MLE series corresponds to the log-normal distribution with a mean of -1.6 and variance 2.12, and SMM series corresponds to the log-normal distribution with a mean of -1.6 and variance 2.62.

(b) Sales distributed Pareto. SMM series corresponds to Pareto with location parameter 0.000059 and shape parameter 0.074 estimated by the SMM approach. MLE series corresponds to Pareto with location parameter 0.000003 and shape parameter 0.13 estimated with the ML approach.
than in the data if their sales came from the same distribution as the sales of the single product exporters.

So far, we have shown that the relationship between the mean best/least selling products and exporter scope arises due to aggregation even in the absence of ex-ante firm heterogeneity. This ability of the statistical model to replicate the sales at rank pattern indicates that comparing sales of the best and least selling products between large and small scope exporters is misleading. In fact, comparing data to the benchmark of the statistical model highlights that large scope exporters sell no more than single product exporters in their top selling products but sell more than single product exporters in their least selling products. This is in contrast to the conclusion that one would reach by directly comparing mean sales at the highest/lowest rank for firms of different scope.

3.2.3 Prediction 3

Next, we address Prediction 3 of the statistical model. In Figures 7(a) and 7(b) we compare average sales per product in the data and simulated from the statistical model with sales distributed log-normally and Pareto. In both figures average sales per product tend to increase with scope in the data and are virtually independent of scope in the simulations. This is consistent with Prediction 3 and suggests that average sales per product is a useful moment to characterize multi-product exporters. Furthermore, average sales in Figures 7(a) and 7(b) suggest that large scale exporters on average sell
Figure 6 – In the simulation, sales are distributed log-normally. The location and shape parameters are estimated from the data on single product exporters only.

(a) Average sales in the least selling product for exporters of different scope.

(b) Ratio of the mean least selling product in the data to the simulated analogue from the statistical model conditional on exporter scope.
more than smaller scope exporters, although the relationship between scope and average sales per product is not monotone.

When sales are distributed log-normally, the statistical model matches the magnitude for average sales per product, even though it does not replicate the relationship between scope and average sales per product in the data. With Pareto distribution, average sales per products predicted by the statistical model depend on how the parameters of the distribution were estimated. Average sales per product based on the SMM estimates provide an unreasonably low estimate of average sales per product, even though the mean sales at rank simulated from the SMM estimates produced a better fit to the data than the moments simulated from the ML estimates. This further highlights that Pareto poorly fits the entire distribution of sales.

3.2.4 Prediction 4

According to Prediction 4, the log ratio of sales between the best selling and the second best selling product is constant with scope when sales are distributed Pareto and decreases monotonically with scope when sales follow log-normal, Weibull or exponential distributions. In Figure 8, we show that when sales are log-normally distributed the mean of the log-ratio decreases with exporter scope both in the data and the simulation. The model misses the levels but replicates the rate of decline in the ratio with scope. Note that we do not directly target the ratio moments in the data.

The relationship between the ratio of sales and the number of products is
Figure 7 – Average sales per product by exporter scope.

(a) Sales distributed Log-Normally.

(b) Sales distributed Pareto.
Figure 8 – Mean ratio of the best selling to the second best selling product.
rarely of interest in its own right. Instead, researchers use the ratio as a measure of skewness of the exporter’s product mix and focus on how competition impacts it. However, to the extent that changes in the competitive environment influence the number of products firms export, some of the variation in the ratio will be driven by the changes on the extensive margin rather than exporter response on the intensive margin. In the next section, we explore when the log-ratio is a useful measure of sales concentration, and when it mechanically reflects the variation in the number of products.

4 Multi-destination Extension

Overwhelmingly, multi-product exporters sell to many destinations and many empirical regularities about multi-product exporters involve variation in rank statistics across destinations. For example, the log ratio between sales of the best and the second best selling product discussed earlier is used to measure firms response to competition intensity at the destination. Another example is correlation between product rankings across destinations is used to capture the role of core-competencies. To understand whether these patterns on the intensive margin arise due to the economic forces or due to randomness and variation in the number of products we extend the benchmark statistical model to take into account multiple destinations.

As with a single destination case, a multi-product exporter indexed by $f$ is a collection of products $K_d$ that a firm exports in a given year to a given
destination $d$. Products that a firm exports to a destination are indexed by $k \in \{1, \ldots, K_d\}$. The number of products a firm exports to a destination $d$ ($K_d$) is treated as exogenous. Product sales $S_{fkd}$ are iid draws from the same log-normal distribution $F()$.

Observations: 176

The sample contains all countries to which at least one Chinese multi-product exporter sold at least two products in 2003 and includes only manufacturing producers. The first three rows describe the variation in the outcome variables across different destinations. The Mean Country Log Ratio is the mean log-ratio of sales of the best selling to the second best selling product at a destination. The Mean Country Scope is the average number of products that firms export to a destination and Number of Exporters is the number of firms exporting to a destination. The table also contains information on the country level variables that we will use to proxy market toughness of a destination: Log GDP, Log Supply Potential, Log GDP per Capita and Log Distance.

To estimate the parameters of the sales distribution $F()$ we use the Maximum Likelihood (ML) approach where we treat sales of the Chinese exporters to 176 destinations as if they come from a single distribution.

Table 3 provides some summary statistics for the country level variables the we use. The sample includes all destinations to which at least one Chinese exporter sold at least two products in 2003 and only includes manufacturing firms involved in production of its exports. The number of multi-product exporters selling to a destination is highly skewed: the median number of exporters is only 82 while the 95th percentile is 2,627. Average exporter
scope, on the other hand, is much more balanced across destinations with the 25th percentile given by 2.6 and the 95th by 3.72. The table also contains information on the determinants of the market toughness (Log GDP, Log Supply Potential, Log GDP per Capita, and Log Distance) that we will use in exploring the effect of competition in on the sales at rank ratio.

In its simplest form the multi-country extension of the model has two parameters: the location and the shape parameter that govern the distribution of sales. In the data, we have to contend with the fact that sales systematically vary with destinations and product categories (6-digit HS categories). To take this into account, we purge the sales of the destination-product category fixed effects. We do this by first estimating Equation 1

\[ \ln S_{fkd} = \gamma_{kd} + \epsilon_{fkd} \]  

where the dependent variable is the log of sales and \( \gamma_{kd} \) captures the destination-product category fixed effects.

We then use the residual \( \epsilon_{fkd} \) to estimate the parameters of sales distribution \( F() \). Using the ML approach and the assumption that \( \epsilon_{fkd} \) is normally distributed, we estimate the variance of 2.14 with a standard error of 0.002 and the mean equal to 0 by construction. Figure 9 compares the estimated theoretical distribution and the actual distribution of the log-sales. While the log-normal distribution slightly underestimates the thickness of the left tail, it is otherwise able to approximate the empirical distribution of log sales.

fairly accurately. We use the estimated distribution to simulate sales data for each exporter at a destination and compare the patterns that arise to those that we observe in the data.

4.1 Ratio of Sales at Rank

In the previous section we have shown that when sales are log-normally distributed the log ratio of sales between the best selling and the second best selling product is systematically related to the number of products a firm sells in the market: smaller scope exporters have a higher ratio. The ratio, in turn, has been used to measure how multi-product firms respond to changes in the intensity of competition. The best known example of this is Mayer et al. (2014). In their seminal paper on multi-product exporters, they show that tougher competition in an export destination shifts down the entire distribution of markups across products and induces multi-product exporters to concentrate on their core products. Sales in the model are distributed Pareto so an increase in sales concentration is equivalent to an increase in the log-ratio. To test the theoretical predictions of their model Mayer et al. (2014) regress the log-ratio of sales between the best and the second best selling product on destination market size, its foreign supply potential, and

---

9 Using raw data on log sales does not change the estimate of the variance. The results can be found in the online appendix.

10 A core product of a firm is its lowest marginal cost product.

11 The supply potential is used to proxy for the geography of a destination that does not rely on country-level data for that destination. It is typically constructed as the aggregate predicted exports to a destination based on a bilateral trade gravity equation (in logs) with both exporter and importer fixed effects as well as the standard bilateral measures of
other variables that proxy toughness of competition in a market\footnote{The regressions include country-specific random effects on firm-demeaned data.}

While \cite{Mayer2014} consider alternative measures of concentration, their preferred formulation of the model’s testable prediction relies on the log-ratio. As long as firm-product sales are distributed Pareto, using log-ratio to capture the reallocation of resources across the fixed product range is a perfectly valid approach. However, this is unlikely to be the case in the data, and the log-ratio is likely to reflect variation in the number of products a firm exports to a market above and beyond the reallocation of resources across products within the firm. This is a problem because exporter scope at a destination itself varies with market toughness. \cite{Bernard2010} and \cite{Feenstra2007}, among others, document that firms export a wider product range to larger markets and trim their scope in high supply potential destinations.

Prediction 4 of the statistical model highlights that the log-ratio is related to the number of products for which it is calculated. Smaller scope exporters have a higher ratio. If firms export more products to large market size destinations then the statistical model predicts a negative correlation between market size and the log-ratio. Pro-competitive effects of a larger market that work through firms reallocating resources to lower cost (higher trade barriers/enhancers. Following \cite{Mayer2014} the foreign supply potential is a related measure of a destination’s foreign supply potential that does not use the importer’s fixed effect when predicting aggregate exports to that destination. By construction, foreign supply potential is thus uncorrelated with the importer’s fixed-effect. The supply potential data by \cite{Head2011} is available online at \url{http://www.cepii.fr/anglaisgraph/bdd/marketpotentials.htm}.}
mark-up) products in contrast imply a positive correlation. It’s even trickier with the supply potential. This implies that firms export fewer products to high supply potential destinations, so the statistical model predicts a positive correlation between the log-ratio and the market supply potential. Pro-competitive effects captured by the high-supply potential also imply a positive correlation with the log-ratio. So, when one regresses the log-ratio on the measures of market competitiveness, the coefficients reflect a combination of product mix adjustments and product scope adjustments. To the extent that one wants to measure the effects of competition on the reallocation of resources across a given product range, one will underestimate the effect of market size on changes in product mix and overestimate the effect of market supply potential.

Whether variation in the number of products exported to a destination is sufficient to generate statistically significant relationships between the log-ratio and the variables that proxy intensity of competition in the market is an empirical question. To answer we then simulate the statistical model to obtain a data set where firm outcomes are driven by randomness alone. We then replicate the regressions in Mayer et al. (2014) to evaluate the impact of the market competitiveness measures on the log-ratio in the actual and simulated data sets. Any statistically significant results using the simulated data set will indicate that the results are driven by variation in the number of products rather than changes on the intensive margin.

Before we make use of the simulated data, we establish the relationship
between the ratio and the various measures of market toughness in the Chinese data by replicating the regressions from Table 2 in Mayer et al. (2014) in columns (1) and (5) in Table 4. In column (1), we look only at the effect of market size and foreign supply potential. In column (5), we also include geographic barriers. Only the log of GDP variable is highly significant across regressions. In magnitude, the coefficient on the $\log$ GDP variable is similar to what Mayer et al. (2014) find for the French exporters. To the extent that GDP captures the intensity of competition, we observe that the effect on the log-ratio is positive - firms concentrate their resources in their best selling products in tougher markets. The foreign supply potential that is significant in French data is not significant in any of the formulations in the Chinese data.

Next, we reproduce the regressions with the simulated data in columns (3) and (7). In the simulated data, the product sales are just iid draws from the log-normal distribution. Hence any effect of market competitiveness measures that we find is driven by aggregating data on sales across the different number of products to the firm level. If a lot of small scope exporters sell at a destination, the ratio will be mechanically higher than if the destination was dominated by large scope exporters. Both in columns (3) and (7) the coefficient on GDP is negative and significant, reflecting that large market size is associated with firms exporting more products, which mechanically lowers the log-ratio. The coefficient on the foreign supply potential variable is positive in both regressions. Interestingly it becomes significant in the sim-
ulated data when we control for bilateral trade barriers between China and its trading partners in column (7). This is because including both geographic barriers and supply potential helps differentiate between good geography and distance as many high supply potential markets are located far away from China.\(^{13}\) Distance and contiguity in column (7) are also statistically significant. The log of distance enters with a negative sign, while contiguity has a positive effect. These signs are consistent with firms exporting a narrow range of products to faraway destinations and a wider range to countries nearby.

To check that the variation in the simulated data is indeed driven by the variation in scope, we use the number of products as the dependent variable in columns (4) and (8) respectively. The signs on the independent variables are consistent with variation in scope being responsible for the variation in the log-ratio in the regressions with the simulated data.

Finally, we introduce the scope variable as an additional control in the regressions with the data on Chinese exporters. In columns (2) and (6) we regress the log-ratio on exporter scope along with the measures of market competitiveness. In both cases the coefficient on the scope variable is negative and statistically significant. What is more interesting is that the inclusion of the scope variable changes the magnitude of the market size coefficient. Comparing the regressions in column (1) and (2,) the coefficient on

\(^{13}\)In the French data that Mayer et al. (2014) use distance from France is highly correlated with good geography and hence a high supply potential for that destination. The correlation between the log-distance and log-supply potential is 78 percent. This is not the case in the Chinese data, the correlation between the foreign supply potential and distance in logs is negative and relatively small (-0.2191).
the GDP variable increased from 0.035 to 0.05, which is a 30 percent increase. Similarly, the coefficient on the GDP variable increases from 0.034 in column (5) to 0.05 in column (6), an increase of 32 percent. This shows that the coefficients on market size in columns (1) and (2) underestimate the effect of market size on the reallocation of sales across products because it also captures variation in the number of products exported to the destination. This further indicates that the effect of market size in Mayer et al. (2014) could have been underestimated by as much as 30 percent. The coefficient on the supply potential variable is still statistically insignificant, but changes the sign from positive to negative again implying that in the original formulation the coefficient underestimates the negative effect of the supply potential on product mix. Note, however, that the scope and product mix (which we approximate with the log-ratio) are likely to be simultaneously determined so using scope as an independent variable is not econometrically correct.

In Table 4 the regressions estimated from the simulated data highlight that variation in the number of products can drive variation in the log-ratio even when firms don’t optimize on the intensive margin. As such, the log-ratio may be less than an ideal measure of changes in sales concentration in response to changes in competition. We have shown that the coefficient on the market size is biased downward, while the coefficient on the foreign supply potential is biased upward. This has implications for the measures of economic significance of the product mix adjustment mechanism. The GDP coefficient in the baseline regression can be interpreted as the average elastic-

ity of the log-ratio with respect to the destination’s GDP. [Mayer et al. (2014)] use this elasticity to estimate that the within-firm resource reallocation on the intensive margin contributes 19 percent to the aggregate productivity growth. Our results suggest that the true effect of GDP on skewness measured by the log ratio of sales is larger than the baseline regression estimates, and would imply that [Mayer et al. (2014)] underestimate the contribution of the product mix channel to aggregate productivity growth.

More generally, the results of this section illustrate that the log-ratio, as well as other measures that are based on order statistics, should be treated with care in the multi-product firm analysis as they systematically vary with the number of products per firm.
4.2 Correlation Between Global and Local Ranks

In their paper [Eckel and Neary (2010)] they propose a core-competency model of a multi-product firm where a core product has a lower marginal cost than peripheral products. In the context of multi-product exporters the core-competencies imply that firms will sell their core varieties in larger amounts across destinations and all else constant the same core product should dominate the product ladder at each destination. One way to assess the empirical relevance of core-competencies is to compare product rankings across destinations by calculating the correlation between domestic and home product rankings, or global and local product rankings.

One reason why core-competencies became a prominent feature of many multi-product exporter models (Arkolakis et al. (2020), ?) is that significant correlation between global and local rankings has been documented across a number of data sets. [Arkolakis et al. (2020)] show that in Brazilian data the Spearman rank correlation between products exported to Argentina and to elsewhere is 0.86. For French exporters, ? show that correlation between global and local product ranks is 0.67.

In this section we focus on the correlation between global and local ranks. First, we show that moderate correlation between product rankings can arise in the statistical model in the absence of core-competencies. Hence, in models without core-competencies where demand (or cost) shocks are completely random and are uncorrelated across destinations (as in [Bernard et al. (2011)]) correlation is far from negligible. This highlights that correlation between
product ranks should be compared to the correlation that arises when sales are random rather than to 0 correlation. However, when comparing data to the results from the simulation of the statistical model, correlation between global and local rankings is 10% higher in the data than in the simulations which confirms the empirical relevance of core-competencies for multi-product exporters.

Second, we explore how correlation varies with the number of destinations and exporter scope. Our simulations show that correlation decreases with the number of destinations and increases with exporter scope. Which effect dominates depends on the distribution of products across destinations. When products of a firm are distributed equally across destinations (firms export the same number of products to each destination) then increase in correlation due to increase in the number of products is negligible. However, when products are concentrated in few destinations (firm exports all products to one destination and only one product to all the other destinations) then the increase in correlation due to increase in the number of products is more prominent.

This section proceeds as follows. We first show how correlation between global and local ranks varies with the number of destinations and exporter scope. Second, we compare the correlation that we observe in the data to the correlation that arises when we simulate the statistical model for the number of destinations and products we observe in the data. The differences between the correlation in the actual and simulated data reflects variation that can
be attributed to core-competencies alone.

To assign a global and local rank to each product we follow the methodology of Mayer et al. (2014). The local rank is based on product contribution to total sales at the destination. A product that contributes the biggest share to total sales at a destination has rank 1. The global rank is based on a product’s contribution to total sales of the firm across destinations, so, we assign rank 1 to a product that contributes the most to the firm total sales.

Figures 10 and 11 show correlation between global and local ranks as a function of exporter scope and the number of destinations served. To generate the figures we simulate 10,000 firms exporting between 2 and 20 products to up to 20 destinations. Firm-product sales are iid draws from the log-normal distribution with the location parameter 0 and scale parameter 2.24. (The distribution parameters were obtained from fitting the extension of the statistical model to multiple destination to the data.) In Figure 10 the correlation between global and local ranks on the vertical axis is plotted against the number of destinations and each curve corresponds to a different number of products the firm exports. Figure 11 plots the same data, however, it plots the number of products on the horizontal axis and each curve corresponds to the different number of destinations.

In Figures 10(a) and 11(a) each firm exports the same number of products to each destination. The correlation ranges from 0.13 to 0.58. Comparing Figures 10(a) and 11(a) indicates that correlation is highest when the number of countries is small and the number of products is large. Correlation rapidly
decreases as the number of countries to which firms export increases. This is an intuitive result: as the number of destinations increases the number of possible permutations in the local ranks increases making it more likely that global and local ranks differ. Less ex-ante obvious result is that correlation increases with the number of products. To see the intuition for this result note that when sales are iid distributed, as the number of products increases the value of sales at a given rank becomes more extreme (e.g., the maximum of the random sample increases with the sample size). The more extreme are the sales at rank values at a given destination the more influence they exert on the global rank (via the sum of sales across destinations for a given product). Thus the correlation between the global and local product rankings increases with exporter scope. When firms export the same number of products to each destination the decrease in the correlation with the increase in the number of destinations dominates the increase in the correlation that comes from the increase in the exporter’s global scope.

In Figures 10(b) and 11(b) we simulate data in such a way that exporters sell all of their products at the first destination and only sell one product at the remaining destinations. This results in an unequal distribution of products across destinations (contrast this to Figures 10(a) and 11(a) where each firm exports all to each destination). The simulations highlight that the effect of exporter scope and the number of destinations depends on how many products are distributed across destinations. When products are concentrated in one destination the correlation increases steeply with the number
of products.

Overall, the simulations in Figures 10 and 11 show that correlation between global and local ranks is not negligible even when sales are iid distributed and depends on the exporter scope and the number of destinations in a non-trivial way.

In real data on exporting firms each firm exports a different number of products to each destination. To understand how core-competencies impact the correlation between product local and global rankings in real data we compare the correlations in the data and correlations that arise from the statistical model. With the number of products and destinations in the simulation taken from the data the difference between actual and simulated correlation reflects the differences in the way the sales data is generated. In the top panel of Table 5 we calculate the correlations for the Chinese exporters in 2003 and in the bottom panel we calculate the correlation from the simulated data. We simulate the data from the statistical model where product-firm sales are drawn from the log-normal distribution with mean 0 and variance 2.14 and we take the number of products a firm exports to a destination as given. In the simulations (the bottom panel of Table 5) the correlation increases with the number of products that exporter sells and decreases with the number of destinations. Correlation is highest for firms that sell a few products to few destinations. For example, correlation between global and local ranks in the simulated data for exporters that sell 10-19 products to only 3 destinations is 86.2. On the other hand, the correlation
**Figure 10** – Global and local rank correlation by the number of countries

(a) Each firm exports the same number of products to each destination.

(b) Each firm exports all of its products to the first destination and a single product to the remaining destinations.

The scope variable corresponds the total number of products that a firm exports across destinations. We simulate 10,000 exporters with a given scope and exporting to a given number of destinations assuming that each firm exports the same number of products to each destination.
Figure 11 – Global and local rank correlation by the total number of exported products

(a) Each firm exports the same number of products to each destination.

(b) Each firm exports all of its products to the first destination and a single product to the remaining destinations.

The scope variable corresponds the total number of products that a firm exports across destinations. We simulate 10,000 exporters with a given scope and exporting to a given number of destinations assuming that the number of products is unequally distributed across destinations. Each firm exports all of the products to the first destination and only one product to all other destinations.
for exporters that sell 3 products to 10-19 destinations is only 31.16. Overall, this table shows that significant correlation between global and local ranks can arise in the absence of core-competencies.

Comparing the top and the bottom panels of Table 5, the correlation in the actual data exceeds correlation in the simulation for any number of products and destinations. This confirms that correlation between the global and local ranks reflects core-competencies. The difference in the level of correlation in the simulated and actual data increases as we restrict sample to exporters that sell to many destinations and is only moderate when we compare exporters with many products that only sell to a few destinations.

Correlation between products’ global and local ranks conditional on the number of destinations and number of products a firm exports.
In Table 6, we reproduce Table 1 from Mayer et al. (2014) for the Chinese exporters. Each cell reports the correlation between global and local rankings for firms that export at least the number of products given in the top-row to at least the number of destinations given in the leftmost row. The cell on the intersection of column two and row three reports the correlation for exporters that have global scope of at least two and exports to at least 3 destinations. The top panel reports correlation from the actual data and the bottom panel reports correlation for the simulated data. Correlation in the actual data exceeds that in the simulated data across the board. However, it is worth mentioning that correlation in the simulated data is not negligible which highlights the danger of comparing the correlation between global and local rankings to the benchmark of 0.

</table>

The table presents the rank correlation between the global and local ranks for firms that export at least to $n$ countries and at least $k$ products. We do not control for product selection, thereby any product that is not exported to a destination is dropped from local rankings. The top panel Data shows the correlation in the data for Chinese exporters in 2003. The bottom panel, Simulation, shows the rank correlation obtained when we simulate sales for each firm-product pair as iid draws from $LN(0, 2.24)$.

5 Conclusion

In this paper we propose a stark statistical model of multi-product exporters to help separate which well-documented facts about them are genuinely informative about the economic forces behind the observed outcomes, and which ones arise as an artifact of aggregating data across a different number of products. Our results show that patterns that rely on order statistics should be treated with caution. While large scope exporters sell more in their top selling products than small scope exporters, these differences can be repro-
duced with a model where pure chance drives exporter sales per product. In fact, if large scope exporters drew sales from the same distribution as the single product exporters, the differences between the large and small scope exporters would be even bigger. These differences will be bigger the bigger the variance of firm-product sales. Hence, one should be cautious when interpreting the observation that large scope exporters sell more in their top selling products than small scope exporters as evidence of large scope exporters being more productive. Similarly, differences between how much large and small scope exporters sell in their least selling products can be rationalized by randomness and aggregation and so should not be used as evidence for large scope exporters benefiting from lower product introduction fees.

In the context of multi-product exporters we show that using order statistics as dependent variables should be treated with caution as well. For example, we show that the ratio of the best selling to the second best selling product that is often used as a measure of exporter product mix systematically varies with scope. So, when used as a dependent variable to measure changes in the product mix in response to variation in measures of market toughness, it may produce biased results. This occurs when independent variables proxying market toughness are correlated with exporter scope.

Ultimately, in this paper we have shown that comparing outcomes between the large and small scope exporters when it involves aggregating product level data to the firm level may be misleading when order statistics are
involved. Our insight is that this process of aggregation when combined with pure random chance itself gives rise to differences between large and small scope exporters.

6 Appendix

A Proof of Prediction 4

A.1 Pareto distribution

Let $S_{f_k}$ be iid draws from the Pareto distribution with cdf:

$$F(S_{f_k}) = 1 - \left( \frac{S_{f_k}}{a} \right)^{-v} \quad (2)$$

where $a$ is the location parameter such that $S_{f_k}$ and $a > 0$, $v > 0$ is the shape parameter. Let $X_{i:n}$ and $X_{i:n}$ be the $i^{th}$ and the $j^{th}$ order statistic from the random sample of size $n$ from $F(S_{f_k})$. With $i < j$ the ratio $Z_{i:j} = \frac{X_{i:n}}{X_{j:n}}$. Using the inverse Mellin’s transform Malik and Trudel (1982) show that the distribution of the ratio is

$$h(z_{i:j}) = \frac{v z_{i:j}^{v+en-vj-1}}{B(j - i, n - j + 1)} \ast (1 - z_{i:j}^v)^{j-i-1} \quad (3)$$
where 0 ≤ z ≤ 1 and 0 < i < j ≤ n.

Letting j = n and the i = n − 1, the expression in 3 reduces to

\[ h(z_{n-1:n}) = v z_{n-1:n}^{-1} \]  

(4)

The expression \( h_{n-1,n}(z) \) is independent of the sample size, and so will be the expected value of \( E[\ln(1/z_{i:j})] \)

A.2 Weibull distribution

Let \( S_{fk} \) be iid draws from the Weibul distribution with cdf:

\[ F(S_{fk}) = 1 - e^{-\frac{S_{fk}}{\theta}} \]  

(5)

where \( S_{fk} > 0, \alpha > 0, \theta > 0 \). Let \( X_{j:n} \) and \( X_{i:n} \) be the \( i^{th} \) and the \( j^{th} \) order statistic from the random sample of size \( n \) from \( F(S_{fk}) \). With \( i < j \leq n \) the ratio \( Z_{i:j} = \frac{X_{i:n}}{X_{j:n}} \). Using the inverse Mellin’s transform Malik and Trudel (1982) show that the distribution of the ratio is

\[ h(z_{i:j}) = \frac{n!}{(i-1)!(j-i-1)!(n-j)!} \sum_{r=0}^{j-i-1} \sum_{s=0}^{i-1} (-1)^{r+s} \frac{\alpha z^{\alpha-1}}{[(n-j+r+1) + (j-i-r+s) z^{\alpha}]^2} \]  

(6)

where 0 ≤ z ≤ 1 and 0 < i < j ≤ n.

Letting j = n and the i = n − 1, the expression in 6 reduces to:
The expression $h_{n-1,n}(z)$ depends on the size of the sample from which the ordered statistics are calculated, and so will be the expected value of $E[\ln(1/z_{i:j})]$. The expected value of $E[\ln(1/z_{i:j})] = E[\ln(1/z_{i:j})]$

Interchanging summation and integration order obtain:

$$-n(n-1) \sum_{s=0}^{n-2} (-1)^s \binom{n-2}{s} \frac{\alpha z^{\alpha-1}}{[1 + (s + 1)z^\alpha]^2}$$

The integral

$$\int_0^1 \frac{\ln(z) \alpha z^{\alpha-1}}{[1 + (s + 1)z^\alpha]^2} dz_{n-1:n} = -\frac{\ln(2 + s)}{(s + 1)\alpha}$$
Figure 12 – $E[\ln(X_{n:n} - \ln(X_{n-1:n})]$ as a function of the size of the ordered sample drawn from Weibull distribution

\[
E[\ln(1/z)] = -n(n-1) \sum_{s=0}^{n-2} (-1)^s \binom{n-2}{s} \left( -\frac{\ln(2+s)}{(s+1)\alpha} \right)
\]

\[
= \frac{1}{\alpha} \sum_{s=0}^{n-2} (-1)^s \binom{n}{s} \frac{\ln(2+s)}{(s+1)}
\]

The expected value of the ratio drawn from the Weibull distribution is given by the oscillating sum and in general cannot be shown to be monotonically decreasing or increasing in the size of the sample $n$. However for small value of $n$ it can be shown to be monotonically decreasing in $n$. 

67
A.3 Log-normal distribution

Let $S_{fk}$ be iid draws from the log-normal distribution with cdf:

$$F(S_{fk}) = \frac{1}{2} + \frac{1}{2} \text{Erf} \left( -\frac{(\ln S_{fk} - \mu)^2}{2 \sigma^2} \right)$$  \hspace{1cm} (8)

where $S_{fk} > 0$, $-\infty \leq \mu \leq \infty$, $\sigma > 0$. $X_{j:n}$ and $X_{i:n}$ are the $i^{th}$ and $j^{th}$ order statistic from the random sample of size $n$ from $F(S_{fk})$. With $i < j \leq n$ the ratio $Z_{i:j} = \frac{X_{j:n}}{X_{i:n}}$. In the case of log-normal distribution it is not possible to derive the distribution of the ratio for an arbitrary $n$. Instead we adopt numerical integration approach and calculate the expected log-ratio for various values of $\mu$ and $n$.

The joint distribution of two order statistics $X_{j:n}$ and $X_{i:n}$ such that $0 < X_{i:n} \leq X_{j:n} < \infty$ is given by

$$g(X_{j:n}, X_{i:n}) = \frac{n!}{(i-1)!(j-i-1)!(n-j)!} F^{n-1}(X_{i:n}) [F(X_{j:n}) - F(X_{i:n})]^{j-i-1}$$

$$[1 - F(X_{j:n})]^{n-j} f(X_{j:n}) f(X_{i:n})$$

Letting $j = n$ and $i = n - 1$ obtain

$$g(X_{n-1:n}, X_{n:n}) = n(n-1) F^{n-2}(X_{n-1:n}) f(X_{n:n}) f(X_{n-1:n})$$

The expected value of $E \left[ \ln \left( \frac{X_{i:n}}{X_{i:n}} \right) \right]$ or $E \left[ \ln(X_{j:n}) - \ln(X_{i:n}) \right]$
Figure 13 – $E[\ln(X_{n:n} - \ln(X_{n-1:n}))]$ as a function of the size of the ordered sample drawn from log-normal distribution.
\[ E \left[ \ln \left( \frac{X_{j:n}}{X_{i:n}} \right) \right] = \int_{0}^{\infty} \int_{X_{n:n}}^{\infty} (\ln(X_{n:n}) - \ln(X_{n-1:n})) g(X_{n:n}, X_{n-1:n}) dX_{n:n} dX_{n-1:n} \]

While the integral is hard to evaluate analytically we show results of numerical integration in the table below. The expected value decreases with the size of the ordered sample. The decrease is particularly important for small samples.

B Quantifying the Fit

To quantify the fit of the statistical model we use a modified version of \( R^2 \) which measures its ability to explain the sales at rank pattern. Let \( r_{kk}^D \) be the expected value of sales of a product with rank \( k \) for firms with \( K \) products calculated from the data; let \( r_{kk}^S \) be the simulated analogue, and let \( \bar{r}^D \) be the simple mean of sales in the data. \( G \) is given in Equation 9

\[ G = 1 - \frac{\sum_{k,K} (r_{kk}^D - r_{kk}^S)^2}{\sum_{k,K} (r_{kk}^D - \bar{r}^D)^2} \quad (9) \]

and it measures the share of variation in the order statistics explained by the statistical model relative to the share of variation explained by the simple mean. The values of \( G \) for the log-normal distribution and Pareto respectively are shown in Table 7. The statistical model when sales are log-normally distributed accounts for 99.3 percent of variation in order statistics.
with ML estimates and 99.9 with SMM. Pareto distribution, in contrast, performs worse than a simple average of sales with the SMM estimate and accounts for 83.2 percent with ML estimates. The results show that if sales are distributed log-normally then the statistical model replicates the variation in sales at rank much better than if sales are Pareto distributed.

**Table 7** – The value of G for simulated method of moments and maximum likelihood estimators for the log-normal and Pareto distributions.
